SYSTEMATIC REVIEW

The Effectiveness of Care Bundles Including the Braden Scale for Preventing Hospital Acquired Pressure Ulcers in Older Adults Hospitalized in ICUs: A Systematic Review

Abstract:

Background: Despite technological and scientific advances, Hospital Acquired Pressure Ulcers (HAPUs) remain a common, expensive, but preventable adverse event. The global prevalence ranges from 9% to 53% while three million people develop HAPUs in the United States and 60,000 people die from associated complications. HAPU prevalence is reported as high as 42% in ICUs costing on average $48,000 to clinically manage.

Objective: The purpose of this systematic review was to evaluate the effectiveness of multi-component interventions (care bundles), incorporating the Braden scale for assessment, in reducing the prevalence of HAPUs in older adults hospitalized in ICUs.

Methods: This was a systematic review of the literature using the Cochrane method. A systematic search was performed in six databases (CINAHL, Cochrane Library, Google Scholar, JBI Evidence-Based Practice Database, PubMed, and ProQuest) from January 2012 until December 2018. Bias was assessed with the Critical Appraisal Skills Programme Checklist, and the quality of evidence was evaluated with the American Association of Critical-Care Nurses Levels of Evidence.

Results: The search identified 453 studies for evaluation; 9 studies were reviewed. From the analysis, pressure ulcer prevention programs incorporated three strategies: 1) Evidence-based care bundles with risk assessments upon admission to the ICU; 2) Unit-based skincare expertise; and 3) Staff education with auditing feedback. Common clinical management processes included in the care bundles were frequent risk reassessments, daily skin inspections, moisture removal treatments, nutritional and hydration support, offloading pressure techniques, and protective surface protocols. The Braden scale was an effective risk assessment for the ICU. Through early risk identification and preventative strategies, HAPU programs resulted in prevalence reduction, less severe ulcers, and reduced care costs.

Conclusion: Older adults hospitalized in the ICU are most vulnerable to developing HAPUs. Early and accurate identification of risk factors for pressure is essential for prevention. Care bundles with three to five evidence-based interventions, and risk assessment with the Braden scale, were effective in preventing HAPUs in older adults hospitalized in intensive care settings. Higher quality evidence is essential to better understanding the impact of HAPU prevention programs using care bundles with risk assessments on patient outcomes and financial results.

Keywords: Pressure ulcer, Hospital-acquired pressure ulcers, Multi-component interventions, Care bundle, Skin assessment, Braden scale, Intensive care unit, Older adults, Geriatric.

1. INTRODUCTION

Despite technological and scientific advances, Hospital-Acquired Pressure Ulcers (HAPUs) are among the top five most common causes for adverse patient outcomes [1, 2]. For years, the global HAPU prevalence has ranged from less than 1% to more than 40% [3], with a mean prevalence of 14.8% [4]. In American hospitals, the prevalence is estimated to be 0.4% to 38% [5]. Each year, nearly 3 million people develop HAPUs [6] in the United States, costing $10 billion with a $48,000 average charge per ulcer [7]. More than 60,000 acute care patients die from complications related to HAPUs [8], yet as many as 95% are preventable [7]. For this reason, Hibbs [9] noted HAPUs are ‘an epidemic under the sheets’.

Pressure ulcers are a serious but common adverse event for older adults [10]. Within one week of hospital admission, about 15% of patients more than 60 years old will develop a pressure ulcer [11], with an average unadjusted inpatient cost of $66,064 versus $35,844 for patients with and without HAPUs [12]. The additional hospital stay related to a HAPU is on average 4 to 6 days, reducing the availability of beds for other admissions [13]. Hospital payments for managing HAPUs were eliminated in the United States [14], resulting in the financial incentive for risk reduction programs [15]. With hospital-wide implementation of evidence-based practices, HAPUs can be significantly reduced (11.32 cases/quarter) [16].

In the intensive care unit (ICU), HAPU prevalence is reported between 4% to 40% [17], with higher prevalence reported in the medical ICU [18]. HAPUs in the ICU contribute to increased nurse workload, as high as 50%, with at least a 5% impact on the overall budget [19] due to more staffing, medical supply consumption, specialty bed usage, and nutritional support [20]. HAPUs have a deleterious impact on the quality of life for people recovering from illnesses with limited mobility, increased incidence of sepsis, additional surgeries and extended hospital stay [21, 22]. For these reasons, HAPUs are a recognized quality of care surrogate, risk management problem, and patient safety priority for the ICU [17, 23].

1.1. HAPUs and Nursing

Classified as a nursing-sensitive quality indicator [24], HAPUs are acknowledged to be a fundamental nursing responsibility in the ICU [25, 26]. The three independent predictors for HAPU development are generally managed through nursing services in the hospital setting including, mobility and activity, perfusion related to diabetes and other diseases, and skin integrity, including pressure ulcer status [27]. As HAPUs can develop within four to six hours [28], nurses can prevent ulcers by identifying high-risk patients, initiating evidence-based intervention strategies, and monitoring for signs of ulcer development [29]. Pressure ulcer prevention programs have improved with multidisciplinary teams [30] led by nurses as the most knowledgeable about HAPUs, capable of identifying high-risk patients, and available to implement recommended interventions [31].

1.2. Care Bundles and Risk Assessment

Although intervention studies to prevent HAPU development have been conducted in different clinical settings, most employed single interventions in comparison to standard care [32]. However, multi-component interventions, or care bundles, with a risk assessment are more effective in preventing HAPU development [29, 33]. The Braden scale for predicting pressure sore risk [34 - 37], more commonly called the Braden scale [38], is the most widely used tool in hospitals [39] to identify patients at high risk for HAPUs. The Braden scale is highly effective in assessing HAPU risk among patients in medical, surgical, and critical care settings [40], and is more accurate than the clinical judgement of nurses [41].

Care bundles combine evidence-based interventions, usually three to five components, to yield a significantly better outcome than when individually implemented [42, 43]. To maximize the clinical outcome, all the interventions must be performed collectively and implemented consistently [44]. Most HAPU care bundles include a risk assessment, support surfaces, patient repositioning, mobilization, friction reduction, nutritional support and moisture management [45]. Additional intervention strategies include unit-based wound care clinicians, health record monitoring, audit result feedback, staff education, computerized processes, and standardized clinical practices [6].

1.3. Purpose of Systematic Review

Knowledge is translated from research into clinical practice [46] based on the evidence reported by systematic reviews [47, 48]. Yet, there has not been a systematic review of the intensive care literature published since 2002 for HAPU prevention strategies incorporating the Braden scale [49], and none focused on care bundles. The purpose of this systematic review was to evaluate the effectiveness of care bundles incorporating the Braden scale for risk assessment in reducing the HAPU prevalence in older adults hospitalized in the ICU.

2. MATERIALS AND METHODS

This systematic review was guided by the methodological framework outlined by the Higgins & Green [50] through ten steps, including: 1) Frame research question; 2) Construct search strategy; 3) Test search strategy in PubMed; 4) Identify relevant studies for sample; 5) Assess the level of evidence; 6) Evaluate the risk for bias; 7) Extract data from studies; 8) Summarize the data; 9) Interpret the findings; and 10) Report the evidence [51 - 53]. The PICOS (participants, interventions, comparators, outcomes, and study design) technique [54], with the addition of time (PICOTS), defined the searchable research question (Supplemental Table 1). The study was approved by the university institutional review board and reported according to the preferred reporting items for systematic reviews and meta-analyses, or PRISMA [55].

2.1. Search Strategy

A systematic search was performed using thesaurus terms and keywords in six databases, CINAHL, Cochrane Library, Google Scholar, JBI Evidence-Based Practice Database, PubMed, and ProQuest between January 2012 and December 2021.
2018 for research papers reporting experimental, quasi-experimental, and observational study designs. For the search strategy, a combination of search terms and keywords included: pressure ulcer, Braden scale, ICU, pressure ulcer prevention, protocol, intervention, multi-component, and care bundle, combined with Boolean operators (Supplemental Table 2). The inclusion criteria were research studies with three or more interventions (care bundle), male and/or female patients 60 years of age or older, hospitalized in the ICU for at least 24-hours, and without HAPUs upon entry into the unit.

The review leader conducted the pilot search in PubMed, before initiating the searches in six databases with a second reviewer. The search strategy for each database, with keywords, was shared with the second reviewer to ensure the comprehensive search could be repeated in a substantially similar manner. An additional reviewer, an expert in scoping and systematic reviews, provided guidance throughout this process, including testing the search strategy with a qualified biomedical reference librarian.

2.2. Study Selection

Once the search was completed, the titles, abstracts, and full papers were independently assessed by two reviewers in sequential rounds applying the inclusion criteria. The PRISMA [54] four-step process for study review and selection was utilized: a) identification (records identified), b) screening (titles reviewed and abstracts screened), c) eligibility (full-text assessed) and d) included (document included in the sample). When there was not agreement between the two reviewers during the title and abstract screening, the study was included in the next round for further consideration to reduce the opportunity for selection bias. To prevent methodological bias, the Critical Appraisal Skills Programme (CASP) Checklist [57 - 59] (qualitative, randomized control, case-control, cohort, or systematic review) was applied to assess the quality, relevance, and results of each study. At least 70% of the criteria for each checklist needed to be met for inclusion. Any uncertainty or disagreements were collaboratively resolved through a review of the questionable criteria to reach a consensus.

2.3. Data Collection and Analysis

After the sample was defined and the study quality evaluated, data from the included studies were abstracted into an Excel-based literature review matrix for analysis and synthesis. The data abstraction was completed by two reviewers and verified by a third. The quality of evidence was evaluated with the American Association of Critical-Care Nurses Levels of Evidence [60]. Studies assessed within the first four evidence levels (A, B, C, and D) were included in the review, while level M studies were excluded. Studies assessed as the highest level of evidence, or level A, include a meta-analysis of multiple controlled studies or meta-synthesis of qualitative studies with results that consistently support a specific action, intervention, or treatment. The next level, or level B, describes well-designed controlled studies, both randomized and non-randomized, with results that consistently support a specific action, intervention, or treatment. Then, level C studies are qualitative, descriptive, correlational, integrative reviews, systematic reviews, or randomized controlled studies with inconsistent results. Next, level D studies include peer-reviewed professional organizational standards, with clinical studies to support recommendations. Finally, level M are manufacturer recommendations. This leveling facilitated study comparison to identify the strongest evidence for clinical practice [61].

3. RESULTS

From the 453 papers included in the title review, the full texts of 43 studies were reviewed with 34 studies [23, 28, 30, 32, 33, 45, 62 - 89] excluded (Table 1). The final sample of nine studies [90 - 98] (Table 2) met the CASP checklist threshold for inclusion. The complete sampling process is provided in the PRISMA diagram (Fig. 1). Most data extracted for this review originated from studies assessed at level C (n=7), with 1 study at level B and 1 at level D. The studies largely reported quality improvement programs with outcomes focused on care bundles with some addressing implementation strategies such as unit-based expertise in wound care and staff education with audit feedback.

3.1. Hospital Acquired Ulcer Prevention Programs with Care Bundles

In a systematic review comparing intervention effectiveness for a HAPU clinical practice guideline, Qaseem et al. [95] reported care bundles significantly improved skin care and reduced HAPU rates, with a cost savings of at least $3,000 per case. Similarly, Sullivan & Schoelles [96] reported care bundles significantly reduced HAPU rates in 11 (42%), with a mean reduction of 82% (range 67% to 100%). For assessment within the care bundles, there was also no significant difference reported in diagnostic accuracy between the Braden, Cubbin and Jackson, and Norton and Waterlow scales [95].

The single randomized controlled trial (n=140) was reported from Saudi Arabia [98]. In this study researchers compared a care bundle (risk and skin assessments, skincare, nutrition, repositioning, and support surfaces) with a training program for the intervention group to normal care for the control group. HAPU incidence was significantly reduced in the intervention group (7.14%, 5/70 patients) when compared to the control (32.86%, 23/70 patients) [98]. There was also significantly less stage I/II pressure ulcers, with no stage III/IV, development for the intervention group. Differences in care processes were also observed for repositioning (85% every three hours for the intervention group compared to 20% every two hours for the control group) and health protector application (97% for the intervention group compared to 0% control group). Furthermore, a retrospective observational cohort study found there was a longitudinal impact of payment policies on the quality improvement interventions to prevent HAPUs. In this regard, Padula et al. [94] observed hospitals adopting bundled interventions had a 27% reduction in HAPUs (-1.86 cases/quarter; \( p=0.002 \)). The bundled interventions were attributed to changes in reimbursement policy, resulting in a 100% reduction in HAPU cases (-11.32 cases/quarter, \( p<0.001 \)).

3.2. Unit-Based Wound Care Expertise

Three studies [90, 92, 93] reported pressure ulcer prevention bundle implementations with the inclusion of a wound, ostomy, and continence (WOC) clinician and/or

![PRISMA 2009 Flow Diagram](image-url)
skincare champion. In a pre- and post-intervention design, Cano et al. [92] evaluated a multidisciplinary HAPU quality improvement program with an evidence-based protocol, staff education, WOC nurse, and environment of care improvements such as new inpatient support surfaces. The prevalence decreased from 11.7% (stage 2 to 4 ulcers) to 2.1% after program implementation. As the prevalence rose to 5.1% across several quarters, an additional staff education resulted in the continued reduction to 2.8% for 10 consecutive quarters. The program with evidence-based practices, protective products, and staff education reduced the HAPU risk in the short-term, and repeated staff education resulted in the sustained reduction.

In a quasi-experimental pre- and post-intervention study, Anderson et al. [90] compared a universal pressure ulcer prevention bundle and semi-weekly WOC nurse rounds with standard care in a sample of ICU patients (n=327). While the prevention bundle included the same components as the standard care, the interventions differed in length, complexity, number of interventions, and accessibility. Statistically significant differences were observed between the two groups for the pre- and post-intervention results specific to repositioning and elevation of heels for the prevention bundle group. The prevention bundle with expert unit-based wound care was most effective in reducing the HAPU risk.

After experiencing a 27% HAPU prevalence, Kelleher et al. [93] implemented a 36-month quality improvement program in a 17-bed surgical ICU. The average patient age for HAPUs was 57.9 ± 16.7 years, with a mean Braden scale score of 13 ± 1.2 (range, 9-17). The underpinning of the intervention was monitoring Braden subscale scores. Also, peer-to-peer interactions, skin care champion, and a WOC nurse were incorporated to facilitate teamwork and to provide unit-based expertise. During the implementation phase, prevention surface utilization increased 92%, repositioning increased 30%, nutrition assessments increased 77% and moisture management increased 100%.

3.3 Staff Education with Audit Feedback

From a systematic review of interventions, Sullivan & Schoelles [96] reported successful quality improvement programs with care bundles reporting reduced HAPU risk almost always included staff education (25/26 studies) and frequently included staff feedback from audits (12 of 26). In addition, Swafford et al. [97] assessed the effectiveness of a year-long HAPU prevention program in an adult ICU, including the Braden scale, revised skin-care protocol, fluidized repositioners, silicone adhesive dressings, and face-to-face staff education. There was a 69% reduction in HAPUs at the end of the program (45 HAPUs among 10% of patients before and 17 ulcers among 3% of patients after). The authors reported staff education with performance feedback positively contributed to the program outcomes. Similarly, Armour-Burton et al. [91] reported a multidisciplinary healthy skin project eliminated HAPUs in a surgical progressive care unit (mean of 4.85% to 0% for 17 quarters). The key intervention strategies were staff education, unit-based WOC nurse, risk assessment (Braden scale) with the normal care (skin assessments and repositioning, specialty mattresses and dressings, and nutrition support). Finally, Kelleher et al. [93] attributed the elimination of HAPU (from a mean of 27% to 0% for three consecutive quarters) to enhanced education and feedback provided by a WOC nurse. Overall, quality improvement programs with multidisciplinary participation, structured education, and adherence to evidence-based protocols resulted in significant HAPU reductions [91, 93, 97].

4. DISCUSSION

Critically ill people hospitalized in the ICU are more likely to develop a HAPU than other hospitalized people. Older adults are more significantly at risk for serious HAPUs with a more problematic ulcer profile in terms of prevalence, stage, and location. As people with HAPUs have more complications, such as pneumonia and renal failure [99], programs often focus on achieving cost reductions based on reforms in hospital reimbursement rather than clinical outcomes [94]. Despite evidence indicating the hospitals are responding to the reimbursement problem with quality improvement initiatives with evidence-based strategies to identify high-risk patients to prevent ulcer development, program comparison has been obstructed by the lack of uniformity in terms, inconsistent concepts, and dissimilar measurements [100].

The quality of evidence was substantially limited by the mostly single site quality improvement study designs. However, programs incorporating care bundles have been reported to be more effective than single interventions in reducing HAPUs in multiple studies [45, 92, 101]. The care bundle benefits seem to be derived from the synergy created by the different interventions. For example, including a sub epidermal moisture measurement in a care bundle results in the identification of early skin damage four days sooner than a nurse assessment [102]. This is why care bundles have been described as the standard of care to prevent HAPUs [95].

With the care bundles, there are many other changes to note about program effectiveness. In addition to care bundles, hospitals reported educating and training staff, revising assessment protocols, enhancing wound documentation, implementing quality audits with feedback for staff, adopting the Braden scale, and redesigning reporting processes are also important strategies to reduce HAPUs [96]. As the practice setting can influence nursing decisions, the effective programs incorporated teams facilitating the mutual support between nurses and other professionals. Multidisciplinary team success resulted from planned collaboration and effective communication. This may explain the missing relationship between years of practice experience and academic preparation with care bundle adherence [103]. Critical care nurses are often skin care ‘champions’, while WOC nurses, dieticians, and physical therapists are supportive team members.

Educational interventions are not only necessary for implementing care bundles but also for improving diagnostic accuracy and reducing misclassifications with the HAPU risk assessment [104]. Due to inaccuracies in diagnosing, classifying, and reporting pressure ulcer injuries, international guidelines are needed to support standardized clinical assessments, data reporting, and outcomes management [105].
Similarly, educational interventions are essential to reliably identify and classify HAPUs [106] and to assess the accuracy of clinical definitions and classification systems [107]. Standardized programs are an essential strategy to strengthen the clinical comparisons necessary to assess HAPU interventions.

HAPUs remain a leading patient safety problem in the intensive care setting [108] despite new technologies and continued quality improvement projects. For this reason, large multicenter ICU studies, incorporating an experimental design with evidence-based interventions, such as care bundles, including the Braden scale, multidisciplinary teams, evidence-based protocols, and clinical education, need to be undertaken to advance the HAPU science. These studies not only need to report prevalence and patient outcome data, but also explore the benefits afforded by technology to minimize the context of burdensome clinical workload with reliable reminders about ulcer care [109]. Finally, new studies need to focus on data mining in data-rich health systems to develop predictive models to compliment risk assessments, such as the Braden scale, to reduce HAPUs in targeted populations [110].

4.1. Strengths and Limitations

There are six limitations for this systematic review which also serve as recommendations for future researchers. First, there was only one study representing the highest levels of evidence. As most PU prevention interventions were designed as single site quality improvement projects, the study design was primarily before-and-after [29]. Second, the scope of this review was limited to bundled interventions incorporating the Braden scale. This limitation strengthened the review by comparing studies using the same risk assessment with similar interventions. However, studies with stronger evidence but not incorporating the Braden scale could have been excluded. Third, two systematic reviews were included in this review as they addressed complex interventions, care bundles, and organizational features for program implementation, such as staff education. However, the results clearly state the context of these reviews to minimize the potential for bias when weighing the evidence. Fourth, methodological heterogeneity [111] was observed with fundamental differences in study designs, prevalence and incidence reporting, and data collection methods that limited the systematic comparisons for a more robust synthesis. In this regard, standards for measuring and reporting need to be implemented to facilitate more opportunities for comparative HAPU prevention research [112]. Fifth, the largely positive study results observed in this review may be attributed to publication bias [33]. Finally, the sample of studies were primarily reported from the United States which might limit the generalizability of the findings. Despite these limitations, this review addresses a wide gap in the literature specific to HAPU prevention programs and the outcomes of older adults hospitalized in the ICU. This review provides important knowledge to guide the development of replicable quality improvement projects with similar research designs, variable definitions, and intervention strategies.

CONCLUSION

Most HAPU reduction programs are implemented as quality improvement studies with a before-and-after design in a single ICU. However, the available evidence suggests early identification of pressure ulcer risk factors with rapid implementation of mitigation strategies in the form of care bundles reduces HAPUs and decreases health care costs. The Braden scale was most widely used risk assessment and reported to have the highest predictability in ICUs. The most effective programs incorporated care bundles with multi-disciplinary teams, education and training, unit based wound care expertise, and audit feedback to clinicians. There is a lack of multicenter research studies with robust experimental designs using standardized processes, recognized measurements, and uniformed reporting strategies. Randomized controlled trials are essential for evaluating care bundle efficacy and organizational process effectiveness across ICUs.

LIST OF ABBREVIATIONS

CASP = Critical Appraisal Skills Programme
HAPU = Hospital Acquired Pressure Ulcer
ICU = ICU
PRISMA = Preferred Reporting Items for Systematic Reviews and Meta-Analyses
WOC = Wound, Ostomy, and Continence

AUTHORS’ CONTRIBUTIONS

All authors participated in the manuscript submitted for journal review. The following authors were involved in the stated phases of the project: Study conception (NAF); study design (NAF, PAP); data collection (NAF, KAD, LGB, PAP); data analysis (NAF, KAD, LGB); data interpretation (); drafting the manuscript (NAF, LGB, JML, PAP); table development (NAF, KAD, ORL, PAP); substantial revisions to manuscript (PAP, JML, KAD), critical revisions to final manuscript (NAF, PAP, JML, ORL); and senior scholar guidance (JML, PAP).

CONSENT FOR PUBLICATION

Not applicable.

FUNDING

This project was partially supported through a research dissemination grant (VRI-D-2020-10-001-RDG) received from the Universidad Norbert Wiener by Dr. Patrick A. Palmieri to advance positive social change through promoting open-source knowledge for low- and middle-income countries.

CONFLICT OF INTEREST

The authors declare no conflict of interest, financial or otherwise.

ACKNOWLEDGEMENTS

We would like to thank Dr. Mirella Brooks and Dr. Jonas Nguh for their contributions to the development of the protocol for this project.

SUPPLEMENTARY MATERIAL

Supplementary material is available on the publishers web
site along with the published article.
